The wetting problem of fluids on solid surfaces.

Part 1: the dynamics of contact lines

Communicated by Kolumban Hutter, *Darmstadt*

Abstract

The understanding of the spreading of liquids on solid surfaces is an important challenge for contemporary physics. Today, the motion of the contact line formed at the intersection of two immiscible fluids and a solid is still subject to dispute.

In this paper, a new picture of the dynamics of wetting is offered through an example of non-Newtonian slow liquid movements. The kinematics of liquids at the contact line and equations of motion are revisited. Adherence conditions are required except at the contact line. Consequently, for each fluid, the velocity field is multivalued at the contact line and generates an equivalent concept of line friction but stresses and viscous dissipation remain bounded. A Young-Dupré equation for the apparent dynamic contact angle between the interface and solid surface depending on the movements of the fluid near the contact line is proposed.

Key words: contact angle, contact line, dynamic Young-Dupré equation, wetting

1 Introduction

The spreading of fluids on solid surfaces constitutes a significant field of research into the processes met in nature, biology and modern industry. Interfacial phenomena relating to gas-liquid-solid systems take into account

*E-mail:henri.gouin@univ.u-3mrs.fr, telephone: +33 491288407, fax: +33 491288776

contact angles and contact lines which are formed at the intersection of two immiscible fluids and a solid. The interaction between the three materials in the immediate vicinity of the contact line has great effects on the statics and dynamics of flows (Dussan, [6]). Many observations associated with the motion of two fluids in contact with a solid wall were performed (Bataille, [1]; Dussan and Davis, [5]; Dussan, Ramé and Garoff, [7]; Pomeau, [24]). According to the advance or the recede of a fluid on a wall, we observe the existence of an apparent dynamic contact angle when a contact line is moving. This angle, named after Young, depends on the celerity of the contact line, and the motion in the vicinity of the contact line does not seem to be influenced by the behaviour of the total flow (Bazhelakov and Chesters, [2]; Blake, Bracke and Shikhmurzaev, [3]). It is noteworthy that since Young's article on capillarity, [37], the understanding of these phenomena has remained incomplete. For example, it is well known that for Newtonian fluids the total dissipation and the interface curvature at the contact line are infinite (Huh and Scriven, [18]; Dussan and Davis, [5]; Pukhnachev and Solonnikov, [25]). In fact, fundamental questions remain unanswered. Among these are the following:

What is the kinematics of the contact line? Can the fluid velocity fields be multivalued on this line? What is the work of the dissipative forces in its vicinity? Is there slip of the contact line on the solid wall? What is the connection between apparent and intrinsic contact angles?

There are various ways to overcome these difficulties: to consider the slip length on the solid wall (Hocking, [15]; Shikhmurzaev, [32]), to consider one phase as a perfect fluid, the possibility of a thin film as a precursor film on a wall (de Gennes, [9]), the assumption of dynamic surface tension different from the static counterpart (Shikhmurzaev, [32]), the use of non-linear capillary theories such as Cahn and Hilliard's theory of capillarity (Seppecher, [29]), or the direct computation of flows by means of molecular models (Koplik, Banavar and Willemsen, [20]). All these attempts are not able to produce a complete satisfactory answer to the previous questions.

It was noticed by using molecular methods that large amplitude shearing rates reveal a tendency to reorganize the liquid, to facilitate the flow and to reduce the viscosity. This suggests that in reality there may be rheological anomalies around the contact line (Heyes *et al*, [14]; Holian and Evans, [16]; Ryckaert *et al*, [28]).

For condensed matter and far from critical conditions, interfaces which are transition layers of the size of a few Angströms between fluids or between a fluid and a solid can be modelled by surfaces endowed with a capillary energy (Rowlinson and Widom, [27]). Solid walls are rough on a molecular

or even microscopic scale. Moreover, the chemical inhomogeneity due to the nature of the solid or the presence of surfactants changes the surface tension in a drastic way. Nevertheless, roughness for example is taken into account by corrections of the measurement on a mean geometric surface (Wenzel equation in Cox, [4] or Wolansky and Marmur, [36]).

The motion of liquids in contact with a solid wall will be considered in this paper within the framework of continuum mechanics. Knowledge of the equations and boundary conditions which govern the movements of liquids in contact with solid walls and control of the contact line motion are the aim of our study.

We propose a model of the dynamics of wetting for slow movements. To prove its accuracy, we are only considering *partial wetting* when the balance contact angle is theoretically defined without ambiguity (de Gennes, Brochard-Wyart and Quéré, [10]). The liquids are non-Newtonian; so the viscous stress tensor deviates from the Navier-Stokes model for large values of the strain rate tensor. For two-dimensional flows, and in the lubrication approximation, the streamlines have an analytic representation and it is possible to obtain the flows near the contact line. Equations of motion, boundary conditions and some consequences on the contact angle behaviour are deduced.

The notation is that of ordinary Cartesian tensor analysis (Serrin, [30]). In a fixed coordinate system, the components of a vector (covector) \mathbf{a} are denoted by a^i , (a_i) , where $i = 1, 2, 3$. In order to describe the fluid motion analytically, we refer to the coordinates $\mathbf{x} \equiv (x^1, x^2, x^3)$ as the particle's position (Eulerian variables). The corresponding reference position is denoted by $\mathbf{X} \equiv (X^1, X^2, X^3)$ (Lagrangian variables). The motion of a fluid is classically represented by the transformation $\mathbf{x} = \boldsymbol{\varphi}(t, \mathbf{X})$ or $x^i = \varphi^i(t, \mathbf{X})$. It is assumed that $\boldsymbol{\varphi}$ possesses an inverse $\mathbf{X} = \Phi(t, \mathbf{x})$ and continuous derivatives up to the second order except at certain surfaces and curves. The vector \mathbf{V} denotes the fluid velocity. The whole domain occupied by the fluid in Lagrangian variables is D_0 and its boundary is the surface Σ_0 . In Eulerian variables, the fluid occupies the volume D_t with boundary Σ_t corresponding to the fixed regions D_0, Σ_0 in the reference configuration. A moving curve Γ_t on Σ_t in the present configuration corresponds to the moving curve Γ_{0t} on Σ_0 in the reference configuration. The domains $D_0, D_t, \Sigma_0, \Sigma_t, \Gamma_{0t}, \Gamma_t$ must obviously be oriented differentiable manifolds.

To each point of Σ_t a unit normal vector \mathbf{n} (n^i), external to D_t , and a mean radius of curvature, R_m can be assigned. Furthermore \mathbf{Id} is the identity tensor with components δ_i^j . Then $\mathbf{Id} - \mathbf{n} \otimes \mathbf{n}$ (components $\delta_i^j - n^j n_i$) is the

projection operator onto the tangent plane of the surface Σ_t ; let \mathbf{t} denote the unit tangent vector of Γ_t oriented; $\mathbf{n}' = \mathbf{n} \times \mathbf{t}$ is the binormal vector to Γ_t with respect to Σ_t ; it is a vector lying in the surface Σ_t .

2 General kinematics of a liquid at a contact line

Following Dussan and Davis' experiments for contact line movements, [5], the usual stick-adhesive point of view of fluid adherence at a solid wall is disqualified in continuum mechanics. A liquid which does not slip on a solid surface does not preclude the possibility that at some instant a liquid material point may leave the surface. The no-slip condition is expressed as follows:

The velocity of the liquid must equal the solid velocity at the surface.

Figure 1: A liquid L_A (in drop form) lies on a solid surface ∂S . The liquid L_A is bordered with a fluid L_B and a solid S ; Σ_{t1} is the boundary between liquid L_A and solid S ; Σ'_{t1} is the boundary between fluid L_B and solid S , and consequently, $\Sigma_{t1} \cup \Sigma'_{t1} = \partial S$; Σ_{t2} is the interface between liquid L_A and fluid L_B ; \mathbf{n}_1 and \mathbf{n}_2 are the unit normal vectors to Σ_{t1} and Σ_{t2} , exterior to the domain of liquid L_A and the domain of fluid L_B , respectively; the edge Γ_t (or contact line) is common to Σ_{t1} and Σ_{t2} and \mathbf{t} is the unit tangent vector to Γ_t relative to \mathbf{n}_1 ; \mathbf{n}'_1 and \mathbf{n}'_2 are the binormals to Γ_t relative to Σ_{t1} and Σ_{t2} , respectively.

Let a liquid L_A be in contact with (i) a solid body S on an imprint Σ_{t1} of the boundary ∂S of S and (ii) an incompressible fluid L_B along an interface Σ_{t2} (fig. 1). Let, moreover, the mobile surfaces $\Sigma_{t\alpha}$ ($\alpha = 1, 2$) be described by the Cartesian equations $f_\alpha(t, \mathbf{x}) = 0$ ($\alpha = 1, 2$) and let the equations of the common curve $\Gamma_t = \Sigma_{t1} \cap \Sigma_{t2}$ be given by

$$f_1(t, \mathbf{x}) = f_2(t, \mathbf{x}) = 0.$$

For a geometric point M of $\Sigma_{t\alpha}$ with velocity \mathbf{W}_α we obtain the kinematic relation

$$\frac{\partial f_\alpha}{\partial x^i} W_\alpha^i + \frac{\partial f_\alpha}{\partial t} = 0,$$

in which the usual convention that over a doubly repeated index summation from 1 to 3 is understood. With the notations of fig. 1, if we observe that $n_{\alpha i} = \lambda_\alpha (\partial f_\alpha / \partial x^i)$ where λ_α is a suitable scalar, the celerity of the surface $\Sigma_{t\alpha}$ has the value $c_\alpha = n_{\alpha i} W_\alpha^i = -\lambda_\alpha (\partial f_\alpha / \partial t)$. This celerity depends only on the coordinates (t, \mathbf{x}) of M .

Let the velocity of a point of Γ_t be denoted by \mathbf{W} . We shall denote the unit tangent vector to Γ_t relative to \mathbf{n}_1 simply by \mathbf{t} and consequently, $\mathbf{n}'_1 = \mathbf{n}_1 \times \mathbf{t}$, $\mathbf{n}'_2 = \mathbf{n}_2 \times \mathbf{t}$ (see fig. 1). The velocity of the common line is then expressible as

$$\mathbf{u} = (\mathbf{Id} - \mathbf{t} \otimes \mathbf{t}) \mathbf{W}.$$

It is orthogonal to Γ_t and its expression depends only on the coordinates (t, \mathbf{x}) of the point on Γ_t but it is not necessarily tangential to ∂S . Then, $\mathbf{u} = \beta_1 \mathbf{n}'_1 + \beta_2 \mathbf{n}'_2$, where β_1 and β_2 are two scalars. Thus, along Γ_t , $n_{\alpha i} W^i = c_\alpha$ and $c_1 = n_{1i} W^i = n_{1i} u^i = \beta_2 (\mathbf{n}_1, \mathbf{n}_2, \mathbf{t})$, $c_2 = n_{2i} W^i = n_{2i} u^i = \beta_1 (\mathbf{n}_2, \mathbf{n}_1, \mathbf{t})$. Consequently,

$$\mathbf{u} = \frac{c_2 \mathbf{n}'_1 - c_1 \mathbf{n}'_2}{(\mathbf{n}_1, \mathbf{t}, \mathbf{n}_2)},$$

in which $(\mathbf{a}, \mathbf{b}, \mathbf{c})$ is the triple product of the three vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$. Due to the definitions of \mathbf{n}_1 and \mathbf{n}_2 , we remark that $(\mathbf{n}_1, \mathbf{t}, \mathbf{n}_2) > 0$.

The kinematics of fluids in the vicinity of the contact line will be axiomatized as follows:

Σ_{t1} is a part of the surface of the solid S . Liquid L_A adheres to ∂S in the sense of the no-slip condition previously proposed. Σ_{t2} is a material surface of liquid L_A .

At the contact line, the velocity \mathbf{u} may have any direction between \mathbf{n}_1 and \mathbf{n}_2 , depending upon, how the contact line is approached within L_A . On the

solid surface Σ_{t1} of S it is, however, tangential to Σ_{t1} , so that

$$\mathbf{u} = \frac{c_2 \mathbf{n}'_1}{(\mathbf{n}_1, \mathbf{t}, \mathbf{n}_2)} \equiv \frac{(n_{2i} V_2^i) \mathbf{n}'_1}{(\mathbf{n}_1, \mathbf{t}, \mathbf{n}_2)} \equiv -u \mathbf{n}'_1$$

where u denotes the value of the contact line celerity in the direction liquid L_A to fluid L_B and \mathbf{V}_2 is the common velocity of the fluids on Σ_{t2} . The contact line Γ_t is *not* a *material line* of L_A ; its velocity is different from the velocities of the liquid on S and on Σ_{t2} .

Figure 2: Typical two-dimensional motion of fluids in contact on a solid surface with a stationary contact line. The wedges formed by Σ_{t1} , Σ_{t2} and Σ_{t2} , Σ'_{t1} bound the fluids L_A and L_B . The auxiliary surface Σ_{t3} separates L_B into two domains. A control surface Σ'_t together with Σ_{t1} and Σ'_{t1} constitute the boundary of a compact domain D_t of the two fluids. For explanations, see main text.

The motion of the particles of L_A on ∂S and Σ_{t2} is comparable with that of an adhesive tape stuck on a wall, the other edge of the adhesive tape being mobile (fig. 2): for $u > 0$ (or $c_2 < 0$) the particles of L_A belonging to Σ_{t2} are driven towards Γ_t and necessarily adhere to S along Σ_{t1} . For $u < 0$ (or $c_2 > 0$) the result is reversed: the particles of L_A belonging to Σ_{t1} reach Γ_t and are driven towards Σ_{t2} .

In fig. 3 the motion of the fluids is sketched. The two manifolds Σ_{t1} and Σ_{t2} constitute two sheets of the same material surface. The motion of the liquid L_A is represented by using a continuous mapping φ from a half reference space $D_0(L_A)$ bounded by ∂S_0 , see fig. 3, onto the actual domain $D_t(L_A)$

occupied by L_A . The domain $D_t(L_A)$ is included in the dihedral angle formed by Σ_{t1} and Σ_{t2} . The contact line Γ_t is the image of the mobile curve Γ_{0t} on ∂S_0 . Outside Γ_{0t} , the mapping φ is C^2 -differentiable.

Figure 3: In the reference configuration, the two sheets of the same material surface of fluid L_A are represented by a manifold ∂S_0 differentiable along Γ_{0t} . Its image in present configuration, D_t is divided into two differentiable manifolds Σ_{t1}, Σ_{t2} forming a dihedral angle. The common edge Γ_t is the image of a moving curve Γ_{0t} in ∂S_0 . The triad $\mathbf{n}_0, \mathbf{t}_0, \mathbf{n}'_0$, in the reference configuration is transformed by the mapping φ into the triad $\mathbf{n}_1, \mathbf{t}, \mathbf{n}'_1$ or the triad $\mathbf{n}_2, \mathbf{t}, \mathbf{n}'_2$ depending on whether its image is associated with the manifold Σ_{t1} or the manifold Σ_{t2} . For other notations see main text.

A second fluid L_B occupies the supplemental dihedral angle $(\Sigma'_{t1}, \Sigma_{t2})$. The conditions of motion are the opposite to those of L_A . The material surface Σ_{t2} is the common interface between L_A and L_B . Provided the fluids are not inviscid, the velocities of the fluids L_A and L_B are equal along Σ_{t2} . Moreover, for liquid L_A , if $u > 0$, the particles of L_A are driven towards Γ_t and adhere to S along Σ_{t1} . The particles of L_B are also driven towards Γ_t ; if they adhere to S along Σ'_{t1} , the contact line goes through the two fluids L_A and L_B along the solid wall ∂S , (if $u < 0$, a change in the time direction along the trajectories leads to analogous consequences). This is in direct conflict with the fact that Γ_t belongs to the interface Σ_{t2} separating L_A and L_B . To remove this contradiction, *it is possible to separate* the fluid L_B in two parts with a material surface Σ_{t3} (see figs. 2 and 3). Σ'_{t1} and Σ_{t3} are the two sheets of the same material surface for a domain $D'_t(L_B)$ of the fluid L_B within the wedge formed by the dihedral angle $(\Sigma'_{t1}, \Sigma_{t3})$. The sheets

Σ_{t2} and Σ_{t3} constitute two parts of the same material surface for a domain $D_t''(L_B)$ of the fluid L_B within the wedge formed by the dihedral angle $(\Sigma_{t2}, \Sigma_{t3})$. The two domains $D_t'(L_B)$ and $D_t''(L_B)$ with common material surface Σ_{t3} - across which velocity is continuous - constitute two independent fluid domains which do not mix. For the domain $D_t'(L_B)$, the conditions in the vicinity of the contact system are similar to those of liquid L_A . Velocities which are discontinuous and multi-valued on Γ_t , are compatible with the movements of fluids L_A and L_B within the domains $D_t(L_A)$, $D_t'(L_B)$ and $D_t''(L_B)$.

3 Equations of motion and boundary conditions revisited

The fundamental law of dynamics is expressed in the form of the Lagrange-d'Alembert principle of virtual work applied to any compact domain of the two fluids L_A and L_B .

Any compact domain D_t made up of the two fluids L_A and L_B is bounded by Σ_t . The boundary Σ_t is constituted of Σ_{t1} , Σ_{t1}' and a complementary surface Σ_t' which is not in contact with the solid surface ∂S : $\Sigma_t = \Sigma_{t1} \cup \Sigma_{t1}' \cup \Sigma_t'$ (fig. 2). In a Galilean frame, the virtual work due to the forces applied to L_A and L_B (including inertial forces but without forces due to capillarity) is in the general form

$$\int_{D_t} [(\phi_i - \rho a_i) \zeta^i + (p \delta_i^j - Q_i^j) \zeta_{,j}^i] dv + \int_{\Sigma_t} P_i \zeta^i da. \quad (1)$$

Here, dv , da (and later dl) are the volume, area (and later line) increments, ζ denotes any virtual displacement field, ϕ the volumetric forces, ρ the density, \mathbf{a} the acceleration vector, \mathbf{Q} the viscous stress tensor and p the pressure. Moreover, the stress vector \mathbf{P} describes the action of the external media on Σ_t . A contribution along Γ_t is not accounted for.

In continuum mechanics, fluid-fluid and fluid-solid interfaces are differentiable manifolds endowed with surface energies¹. We denote σ_{AB} , σ_{AS} and σ_{BS} , the surface energies of interfaces liquid L_A -fluid L_B , liquid L_A -solid

¹In statistical physics, fluid interfaces are transition layers of molecular size. They are modelled in continuum mechanics with regular surfaces (Rowlinson and Widom, [27]). On a molecular scale, a solid wall is rough; but in continuum mechanics, when the scale of the roughness is vanishingly small relative to the size of the solid wall, the solid wall and the fluid-solid surface energy are modelled with a *differentiable average surface, flat on a microscopic scale* and a *corrected surface energy* (Wolansky and Marmur, [36]).

S and fluid L_B -solid S , respectively. It is usual to define a measure of energy on interfaces denoted by σda , where σ stands for σ_{AB}, σ_{AS} or σ_{BS} following the interfaces between the fluids and the solid. The total energy of capillarity of the interfaces $\Sigma_{t1}, \Sigma'_{t1}$ and Σ_{t2} is

$$E = \int_{\Sigma_t} \sigma da.$$

For any virtual displacement field, the variation of E is (Gouin and Kosiński, [12]),

$$\begin{aligned} \delta E = \int_{\Sigma_t} \left[\delta \sigma - \left(\frac{2\sigma}{R_m} n_i + (\delta_i^j - n^j n_i) \sigma_{,j} \right) \zeta^i \right] da \\ + \int_{\Gamma_t} \left((\sigma_{AS} - \sigma_{BS}) n'_{1i} + \sigma_{AB} n'_{2i} \right) \zeta^i dl, \end{aligned}$$

where the scalar $\delta \sigma$ is the variation of the surface energy σ associated with the displacement $\boldsymbol{\zeta}$; vector \mathbf{n} (n^i) and scalar R_m stand for the unit normal vector and the mean radius of curvature to $\Sigma_{t1}, \Sigma'_{t1}$ or Σ_{t2} , respectively.

The surface energy σ_{AB} between the liquid L_A and the fluid L_B is positive and constant (Rowlinson and Widom, [27]). Generally, a fluid-solid surface energy depends on the fluid which is in contact with the solid, the geometrical and physico-chemical properties of the solid, the microscopic asperities or the presence of a surfactant. The simplest case occurs when the surface energy is defined as a function of the position on the surface ($\mathbf{x} \in \Sigma_t \rightarrow \sigma(\mathbf{x}, t)$).

Hereafter considering such a case, the virtual work due to the forces of capillarity applied to L_A and L_B is simply

$$\int_{\Sigma_t} \frac{2\sigma}{R_m} n_i \zeta^i da - \int_{\Gamma_t} \left((\sigma_{AS} - \sigma_{BS}) n'_{1i} + \sigma_{AB} n'_{2i} \right) \zeta^i dl, \quad (2)$$

and relations (1), (2) lead, after execution of the variations and performing integration by parts in several volume and surface terms, to the expression, denoted by δT , of the virtual work by forces applied to the domain D_t

$$\begin{aligned} \delta T = \int_{D_t} [(\phi_i - \rho a_i - p_{,i} + Q_{i,j}^j) \zeta^i] dv \\ + \int_{\Sigma'_t} \left(P_i + p n_i - Q_i^j n_j \right) \zeta^i da + \int_{\partial S} \left(P_i + \left(\frac{2\sigma_S}{R_m} + p \right) n_{1i} - Q_i^j n_{1j} \right) \zeta^i da \\ + \int_{\Sigma_{t2}} \left(\left(\frac{2\sigma_{AB}}{R_m} + p_A - p_B \right) n_{2i} - (Q_{Ai}^j - Q_{Bi}^j) n_{2j} \right) \zeta^i da \end{aligned}$$

$$- \int_{\Gamma_t} \left((\sigma_{AS} - \sigma_{BS}) n'_{1i} + \sigma_{AB} n'_{2i} \right) \zeta^i dl. \quad (3)$$

Unit normal vectors \mathbf{n}_1 and \mathbf{n}_2 are exterior to the domain of liquid L_A and fluid L_B , respectively; σ_S is called σ_{AS} or σ_{BS} depending upon which fluid is in contact with ∂S , and Q_i^j is called Q_{Ai}^j or Q_{Bi}^j , respectively depending upon which fluid is in contact with Σ'_t and ∂S . We emphasize that it is not necessary for D_t , Σ'_t and Γ_t to be material. Finally, virtual displacements are tangential to the solid surface ∂S (on ∂S , $n_{1i}\zeta^i = 0$).

The expression of the Lagrange-d'Alembert principle is (Germain, [11]):

$$\text{For any } \boldsymbol{\zeta} \text{ such that on } \partial S, n_{1i}\zeta^i = 0, \text{ then } \delta T = 0.$$

We emphasize that this principle is not associated with a variational approach and there is no variational principle in it: δT is not the Frechet derivative of a functional (Gurtin, [13]). Only for equilibrium, and due to the fact that the viscous stress tensor is null, the minimization of energy (this is a variational principle) coincides with this approach. Such a method is relevant to the theory of distributions where $\boldsymbol{\zeta}$ are vector fields of class C^∞ with compact support (Schwartz, [31]).

The equations of motion and natural boundary conditions that emerge from it are as follows:

Equations of motion

$$\rho a_i + p_{,i} = \phi_i + Q_{i,j}^j. \quad (4)$$

Conditions on the liquid L_A - fluid L_B interface Σ_{t2}

$$\frac{2\sigma_{AB}}{R_m} n_{2i} = (Q_{Ai}^j - Q_{Bi}^j) n_{2j} + (p_B - p_A) n_{2i}, \quad (5)$$

which is the dynamic form of the Laplace equation.

Conditions on the boundary Σ'_t

$$P_i = -p n_i + Q_i^j n_j, \quad (6)$$

which is the classical expression of the balance of stresses for viscous fluids.

Conditions on the surface $\partial S = \Sigma_{t1} \cup \Sigma'_{t1}$

Expression (3) of the virtual work and the Lagrange-d'Alembert principle imply: For any $\boldsymbol{\zeta}$ such that on ∂S , $n_{1i}\zeta^i = 0$,

$$\int_{\partial S} \left(P_i + \left(\frac{2\sigma_S}{R_m} + p \right) n_{1i} - Q_i^j n_{1j} \right) \zeta^i da = 0.$$

Consequently, there exists a scalar field χ of Lagrange multipliers defined on ∂S such that (Kolmogorov and Fomin, [19])

$$P_i = Q_i^j n_{1j} - \left(\frac{2\sigma_S}{R_m} + p \right) n_{1i} + \chi n_{1i}. \quad (7)$$

Generally \mathbf{P} is not collinear to \mathbf{n}_1 and χ is an additional unknown scalar.

Conditions on the contact line Γ_t

Due to the condition on ∂S , $n_{1i}\zeta^i = 0$, a virtual displacement is expressed at any point of the contact line Γ_t in the form

$$\boldsymbol{\zeta} = \kappa \mathbf{t} + v \mathbf{n}'_1, \quad (8)$$

where the two scalar fields κ and v are defined on Γ_t . For any field $\boldsymbol{\zeta}$ in the form (8), the contribution of $\int_{\Gamma_t} \left((\sigma_{AS} - \sigma_{BS}) n'_{1i} + \sigma_{AB} n'_{2i} \right) \zeta^i dl$ in relation (3) yields

$$\int_{\Gamma_t} \left((\sigma_{AS} - \sigma_{BS}) n'_{1i} + \sigma_{AB} n'_{2i} \right) (\kappa t^i + v n'^i_1) dl = 0 \quad (9)$$

In the general case, since $\mathbf{n}'_1 = \mathbf{n}_1 \times \mathbf{t}$ and $\mathbf{n}'_2 = \mathbf{n}_2 \times \mathbf{t}$, expression (9) implies

$$\sigma_{AS} - \sigma_{BS} + \sigma_{AB} \cos \theta_i = 0, \quad (10)$$

where θ_i is the angle between \mathbf{n}'_1 and \mathbf{n}'_2 . This angle named *intrinsic contact angle* in the literature (Wolansky and Marmur, [36]), is the angle in a plane that is normal to ∂S and Γ_t between tangents in O parallel to Σ_{t2} and ∂S (see fig. 4).

At point O of the contact line Γ_t , let us consider the section of the L_A - L_B interface in the plane erected by \mathbf{n}'_1 and \mathbf{n}'_2 . Let the curvature of the planar section C_{t2} of Σ_{t2} be R^{-1} . For a two-dimensional flow, the mean curvature of the surface Σ_{t2} is $2R_m^{-1} = R^{-1}$. At a generic point of C_{t2} , the angle between \mathbf{n}'_1 and the tangent to C_{t2} is denoted by θ . This angle depends on the choice of the point and on the fluid flow. Since the surface energy σ_{AB} between two fluids is constant and $R = dl/d\theta$, we obtain,

$$\int_O^P \frac{\sigma_{AB}}{R} \sin \theta dl \equiv \sigma_{AB} (\cos \theta_i - \cos \theta_p), \quad (11)$$

Figure 4: Cross section C_{t2} of the fluid-fluid interface and the solid wall in the plane $(O, \mathbf{n}'_1, \mathbf{n}'_2)$. The contact line is reduced in this figure to the point O . The intrinsic angle θ_i is the angle between \mathbf{n}'_1 and \mathbf{n}'_2 . At any generic point of C_{t2} , the angle between \mathbf{n}'_1 and the tangent to C_{t2} is denoted by θ ; thus, at the points M , P and A , the angle θ is denoted by θ_m , θ_p and θ_a , (see main text in section 3). The intersections of the tangent lines to C_{t2} in M and P with the axis $O \mathbf{n}'_1$ are denoted by I_m and I_p . The arcs of circles $C(I_m)$ and $C(I_p)$ of centers I_m and I_p and radius $I_m M$ and $I_p P$ intersect the axis $O \mathbf{n}'_1$ at points J_m and J_p , respectively. A point Q of $C(I_p)$ is represented by (ρ, ω) in the polar coordinate system of pole I_p and polar axis $O \mathbf{n}'_1$ (see main text in subsection 5.2).

where θ_p is the value of θ at the point P . Relation (5) yields

$$\frac{\sigma_{AB}}{R} = (Q_{Ai}^j - Q_{Bi}^j) n_2^i n_{2j} + p_B - p_A,$$

and, consequently, relations (10), (11) yield ²

$$\sigma_{AS} - \sigma_{BS} + \sigma_{AB} \cos \theta_p + \int_O^P \left((Q_{Ai}^j - Q_{Bi}^j) n_2^i n_{2j} + p_B - p_A \right) \sin \theta \, dl = 0. \quad (12)$$

²Relation (12) can be proved directly by using the projection on \mathbf{n}'_1 of the balance of forces applied to a liquid L_A - fluid L_B domain containing the fluid interface Σ_{t2} .

4 A creeping flow example of non-Newtonian fluids

4.1 The Huh and Scriven model revisited

To understand more precisely the behaviour of a liquid near a moving solid-liquid-fluid contact line, we reconsider the situation of two-dimensional flows proposed by Huh and Scriven, [18]. Let us recall the main results of their article (see fig. 2):

A flat solid surface in translation at a steady velocity \mathbf{U} is inclined from a flat interface between a liquid L_A and a fluid L_B (here, the angle θ of fig. 4 is constant, independent of the generic point of C_{t2}). The contact line velocity with respect to the solid is $-\mathbf{U}$; thus in the notations of section 2, we obtain $\mathbf{U} = u \mathbf{n}'_1$. In a two-dimensional situation of the plane $(O, \mathbf{n}'_1, \mathbf{n}'_2)$, it is convenient to take the contact line intersection point O as the origin of a polar coordinate system (r, φ) and $O \mathbf{n}'_1$ as the reference polar axis. The two bulks are incompressible Newtonian fluids. In term of the stream function $\psi(r, \varphi)$ for two-dimensional steady flows, the velocity is

$$\mathbf{V} = v_r \mathbf{e}_r + v_\varphi \mathbf{e}_\varphi, \text{ with } v_r = -\frac{1}{r} \frac{\partial \psi}{\partial \varphi}, v_\varphi = \frac{\partial \psi}{\partial r},$$

and $(O, \mathbf{e}_r, \mathbf{e}_\varphi)$ as the mobile polar frame. In the creeping flow approximation of a viscous fluid, Eq. (4) leads to the linearized Navier-Stokes equation and consequently to the biharmonic equation $\nabla^4 \psi = 0$, where ∇^2 and ∇^4 are respectively the Laplacian and bi-Laplacian operators (Moffat, [23]; Bataille, [1]). A solution is in the form:

$$\psi(r, \varphi) \equiv r f(\varphi)$$

which leads to the ordinary differential equation

$$f(\varphi) + 2f''(\varphi) + f^{(IV)}(\varphi) = 0,$$

and thus to the general solution

$$\psi(r, \varphi) = r(a \sin \varphi + b \cos \varphi + c \varphi \sin \varphi + d \varphi \cos \varphi), \quad (13)_1$$

which holds for either fluid.

The boundary conditions at the solid wall and the liquid-fluid interface are:

(i) a vanishing normal component of the velocity at the solid surface and interface,

(ii) continuity of the velocity at the interface,

(iii) continuity of the tangential stress at the interface,

(iv) non tangential relative motion of the fluids at the solid surface except at the contact line.

These eight linear conditions yield the values of coefficients a, b, c, d for the two fluids L_A and L_B . If the dynamic viscosity coefficients are identical, the eight integration constants are:

$$\begin{cases} a_A = -u D(\theta) [\pi - \theta + \sin \theta \cos \theta], \\ a_B = u D(\theta) [(\pi - \theta)(\sin \theta \cos \theta - \theta) + \pi \theta \sin^2 \theta], \\ b_A = 0, \\ b_B = u D(\theta) [\pi \theta \sin \theta \cos \theta - \pi \sin^2 \theta], \\ c_A = u D(\theta) (\pi - \theta) \sin^2 \theta, \\ c_B = -u D(\theta) \theta \sin^2 \theta, \\ d_A = u D(\theta) [(\pi - \theta) \sin \theta \cos \theta + \sin^2 \theta], \\ d_B = u D(\theta) [-\theta \sin \theta \cos \theta + \sin^2 \theta] \end{cases} \quad (13)_2$$

with $D(\theta) = [\theta (\pi - \theta) - (\pi - 2\theta) \sin \theta \cos \theta - \sin^2 \theta]^{-1}$.

No difficulty should arise, in principle, in the determination of a_A, \dots, d_B for two fluids with distinct dynamic viscosity coefficients. The form of the streamlines as obtained by Huh and Scriven are sketched in fig. 2, and the motion of the contact line fits perfectly with the kinematics as outlined in section 2. Furthermore, if $\mu_A = \mu_B = \mu$ for all values of the dynamic contact angle θ , the viscous stress components are

$$\tau_{r\varphi} = -\frac{\mu}{r}(f + f'') \equiv -2\frac{\mu}{r}(c \cos \varphi - d \sin \varphi), \quad \tau_{rr} = \tau_{\varphi\varphi} = 0$$

and the pressure field is given by

$$p = p_0 + \frac{\mu}{r}(f' + f''') \equiv p_0 - 2\frac{\mu}{r}(c \sin \varphi + d \cos \varphi),$$

where p_0 is the hydrostatic pressure (in both formulae phase subscripts have been omitted).

As proved by Huh and Scriven, the dissipation in any domain D_t of the fluids containing the contact line Γ_t , $\left(\int_{D_t} (\mu/2) (f + f'')^2 / r^2 dv \right)$, and the total traction exerted on the solid surface by the fluid interface are logarithmically infinite. Moreover the normal stress across the fluid interface varies as r^{-1} ; furthermore, the stress jump should be balanced by the Laplace interfacial tension $\sigma_{AB} R^{-1}$ and the curvature R^{-1} does increase indefinitely at the contact line. These are all non-integrable singularities.

4.2 A model of non-Newtonian fluid near the contact line

To avoid the previous paradox of an infinite dissipative function at the contact line, we consider non-Newtonian incompressible fluids with a convenient behaviour of the viscous stress tensor. It is experimentally known that the dynamic viscosity μ of polymeric liquids depends on the shear rate $\dot{\epsilon}$. The behaviour prevailing in such situations is not well understood. In a wide variety of technological applications, liquids are subjected to large shear strain forces. A molecular dynamic investigation of liquids subjected to large shear strain rates has been performed by Heyes *et al*, [14]. The shearing action has been found to change the liquid structure and reveals a tendency to reduce the shear viscosity (Ryckaert *et al*, [28]).

In the literature, some empirical formulas for the viscosity obtained by means of a weighted least-squared adjustment were proposed. For example, $\mu(\dot{\epsilon}) \simeq \mu(0) - c \dot{\epsilon}^2$ was suggested as possible form for the viscosity as a function of $\dot{\epsilon}$ (Heyes *et al* [14]). Holian and Evans, [16], proposed a representation in the form

$$\mu(\dot{\epsilon}) \simeq \mu(0) - c\sqrt{\dot{\epsilon}}. \quad (14)$$

Data for the viscosity of an atomic fluid generated by nonequilibrium molecular dynamic were performed by Ryckaert *et al*, [28]. They indicated that for shear rates below $10^{12} s^{-1}$, $\mu(\dot{\epsilon})$ does not differ significantly from $\mu(0)$ but that these previous laws are not extendable when $\dot{\epsilon}$ tends to infinity.

We propose a model where the viscous stress tensor \mathbf{Q} is a function of the strain rate tensor $\mathbf{\Delta} \equiv (1/2) (\nabla \mathbf{V} + (\nabla \mathbf{V})^t)$. For moderate values of $\mathbf{\Delta}$ the fluid is Newtonian and the function is linear. The function deviates from this classical behaviour for large values of $\mathbf{\Delta}$. For an isotropic stress tensor of *two-dimensional* flow, the Rivlin-Ericksen representation theorem (Truesdell and Noll, [34]) leads to a viscous stress tensor in the form $\mathbf{Q} = \lambda \mathbf{I} + 2 \mu \mathbf{\Delta}$ but λ and μ are non-constant functions of invariants of $\mathbf{\Delta}$, and $\mu \mathbf{\Delta}$ is a functional of $\mathbf{\Delta}$ where μ tends to μ_0 (μ_0 being constant) when $\mathbf{\Delta}$ tends to zero.

We propose to use a convenient representation of the μ -behaviour in the form

$$\mu = (1 - e^{-\gamma}) \mu_0 \quad \text{with} \quad \gamma = \left(\frac{1}{\|\mathbf{\Delta}\| \tau_0} \right)^\xi \quad (15)$$

where $\|\mathbf{\Delta}\| = \tau^{-1}$ is the norm of the strain rate tensor, τ_0 is a characteristic time of the fluid and ξ is a small parameter ($0 < \xi \ll 1$). Then, for very high shear rates μ behaves as a step function as expected in Ryckaert *et al*.

To fit with relation (14) when $\dot{\epsilon}$ is close to $10^{12} s^{-1}$, we choose $\xi = 0.2$ and $\tau_0 = 10^{-14} s$ but many other values can be considered and results of the literature are disparate.

In the following, we take $\xi = 0.1$ and $\tau_0 = 10^{-12} s$; then for $\gamma = \gamma_0 \equiv 4.6$, we obtain $\mu = 0.99 \mu_0$. We call this γ_0 -value the *cut-off* coefficient. For $\gamma = \gamma_0$, $\mu \simeq \mu_0$, and the fluid may be considered as Newtonian.

For the Huh and Scriven model of two-dimensional incompressible flows, $\|\mathbf{\Delta}\| = \dot{\epsilon} = |f + f''|/(2r)$. When $u = 1 \text{ mm. s}^{-1}$, due to the γ_0 -value, considerable variations of μ occur from the contact line to a distance of 20 to 30 Angströms. The same holds true on the solid wall when $\theta \in [5^\circ, 175^\circ]$. Outside these distances from the contact line, the fluids can be considered as Newtonian. Then, μ tends to zero for very large values of the shear rate, and \mathbf{Q} is a function of $\mathbf{\Delta}$ which tends to infinity with $\mathbf{\Delta}$, but weaker than a linear function. The total stress tensor of a fluid is always of the form $-p \mathbf{Id} + 2\mu \mathbf{\Delta}$ where $p = \Pi - \lambda$ (here Π notes the hydrostatic pressure). For steady flows, the equation of motion is

$$\rho \text{grad} \left(\frac{1}{2} \mathbf{V}^2 \right) + \rho \text{rot} \mathbf{V} \times \mathbf{V} + \text{grad} p = \mu \nabla^2 \mathbf{V} + 2 \mathbf{\Delta} \cdot \text{grad} \mu + \rho \mathbf{g} \quad (16)$$

where \mathbf{g} denotes the acceleration due to gravity. For a stream function $\psi(r, \varphi) \equiv r f(\varphi)$, we obtain

$$\begin{aligned} \mu \nabla^2 \mathbf{V} &= -\frac{\mu_0 (1 - e^{-\gamma})}{r^2} ((f' + f''') \mathbf{e}_r + (f + f'') \mathbf{e}_\varphi), \\ 2 \mathbf{\Delta} \cdot \text{grad} \mu &= \xi \mu_0 \frac{\gamma e^{-\gamma}}{r^2} ((f' + f''') \mathbf{e}_r - (f + f'') \mathbf{e}_\varphi), \\ \rho \text{rot} \mathbf{V} \times \mathbf{V} &= -\frac{\rho}{r} (f + f'') (f \mathbf{e}_r + f' \mathbf{e}_\varphi). \end{aligned}$$

The inequalities $0 < \gamma e^{-\gamma} \leq 1 - e^{-\gamma}$, $0 < \xi \ll 1$ and the fact that near the contact line $1 \ll \frac{\mu}{r\rho(f + f'')}$ yields the approximate form of Eq. (16)

$$\rho \text{grad} \left(\frac{1}{2} \mathbf{V}^2 \right) + \text{grad} p = \mu \nabla^2 \mathbf{V} + \rho \mathbf{g},$$

which implies

$$\mu \text{rot}(\nabla^2 \mathbf{V}) + \text{grad} \mu \times \nabla^2 \mathbf{V} = \mathbf{0} \quad (17)$$

with

$$\mu \text{rot}(\nabla^2 \mathbf{V}) = -\frac{\mu_0}{r^3} (1 - e^{-\gamma}) (f + 2f'' + f^{(IV)}) \mathbf{k}$$

and

$$\text{grad } \mu \times \nabla^2 \mathbf{V} = \xi \mu_0 \frac{\gamma e^{-\gamma}}{r^3} \left(f + f'' + \frac{(f' + f''')^2}{f + f''} \right) \mathbf{k}$$

where \mathbf{k} denotes the normal vector to the plane of the flows.

From $\xi \gamma e^{-\gamma} \ll 1 - e^{-\gamma}$, we deduce again the Huh and Scriven approximation for the stream function in the form $\psi(r, \varphi) = rf(\varphi)$, with $f(\varphi) + 2f''(\varphi) + f^{(IV)}(\varphi) = 0$.

On the solid wall, adherence conditions are required. This assumption is in agreement with molecular dynamics of fluid flows at solid surfaces: *The non-slip boundary condition appears to be a natural property of a dense liquid interacting with a solid wall with molecular structure and long range force interactions* (Koplick, Banavar and Willemsen, [20]). For the non-Newtonian model and for the creeping flow approximation, the general solution (13)₁ holds true for either fluid. Furthermore, the boundary conditions at the solid wall and at the liquid-fluid interface are the condition (i) – (iv) of subsection 4.1. Consequently, for the non-Newtonian model and for the creeping flow approximation the trajectories and the velocities near the contact line are identical to those of fluids with constant viscosity μ_0 in the Huh and Scriven model.

The dissipation Ξ in the domain $V_l = \{r \in [0, l], \varphi \in [0, \theta], z \in [0, L]\}$ (where z denotes the contact line coordinate) is

$$\Xi = \int_{V_l} \text{tr}(\mu \Delta^2) dv = L \frac{\mu_0}{2} \int_0^\theta \int_0^l \frac{1 - e^{-\gamma}}{r} (f + f'')^2 dr d\varphi.$$

From the inequality $0 < 1 - e^{-\gamma} \leq \gamma$, we deduce

$$\Xi \leq \frac{L \mu_0}{2^{1-\xi}} \int_0^\theta \int_0^l \frac{r^{\xi-1}}{\tau_0^\xi} |f + f''|^{2-\xi} dr d\varphi = \frac{L \mu_0 l^\xi}{\xi 2^{1-\xi} \tau_0^\xi} \int_0^\theta |f + f''|^{2-\xi} d\varphi,$$

which proves that the dissipation is finite at the contact line, since f given by (13)₁, (13)₂ is bounded.

Other calculations yield a bounded total force exerted on the solid surface by the fluid-fluid interface near the contact line, but another problem associated with the fluid-fluid interface curvature still remains unresolved.

5 Study of a curved interface in the vicinity of the contact line

For a Newtonian fluid in two dimensional flows, the fluid interface curvature should increase rapidly as the contact line is approached. This result is in direct conflict with the hypothesis of section 4 that the fluid interface is perfectly flat. Indeed, Huh and Scriven, [18], pointed out *when water at moderate dynamic contact angle wets a surface at 6 mm.min⁻¹, the local radius of curvature would have to be about 10⁵ time greater than the distance to the contact line and the curvature would be imperceptible by optical means.* Nevertheless in such a case, the intrinsic angle θ_i at the contact line may strongly deviate from the angle θ_p , (see fig. 4), which is observed at a point P near, but not at, the contact line.

Let us consider results presented in subsection 4.2; the equation of motion (4), boundary condition (5), and calculations of subsection 4.2 yield the pressure field values for the fluids L_A and L_B ,

$$p_B - p_A = \frac{\mu}{r} ((f'_B + f'''_B) - (f'_A + f'''_A)) \equiv \frac{\mu u}{r} 2\pi \sin \theta D(\theta). \quad (18)$$

As done by Huh and Scriven, we notice that

$$p_B - p_A = \frac{\sigma_{AB}}{R},$$

and consequently,

$$\frac{r}{R} = \frac{\mu u}{\sigma_{AB}} 2\pi \sin \theta D(\theta). \quad (19)$$

For partial wetting, it is easy to compute the value of $2\pi \sin \theta D(\theta)$ numerically; we obtain

$$\frac{\pi}{6} < \theta < \frac{5\pi}{6} \Rightarrow 4 < 2\pi \sin \theta D(\theta) < 15.$$

When the capillary number $C_a = \mu_0 |u| / \sigma_{AB}$ is sufficiently small, (in experiments, C_a is often smaller than 10^{-3}), we deduce $|r/R| \ll 1$; it is all the more true, for a non-Newtonian fluid given by the representation (15), where μ tends to zero at the contact line.

5.1 Two-dimensional steady flows near the contact line

The conditions and the notations are given in subsection 4.2, but the fluid-fluid interface is curved. The cross section of the fluid-fluid interface and

the solid wall is presented on fig. 4. We consider the domain occupied by the two fluids in the immediate vicinity of the contact line and we assume that, along C_{t2}

$$\lim_{r \rightarrow 0} \frac{r}{R} \equiv \lim_{r \rightarrow 0} \frac{r d\theta}{dl} = 0. \quad (20)$$

Thus, in the immediate vicinity of the contact line, we obtain $|r/R| \ll 1$. On fig. 4, at the generic point P of C_{t2} , the intersection of the tangent line with the axis $O\mathbf{n}'_1$ is denoted by I_p . To each point I_p corresponds, in the fluid domains, the arc of a circle, denoted by $C(I_p)$, with center I_p and radius I_pP . To a point Q of $C(I_p)$ corresponds the polar coordinates, (ϱ, ω) , associated with the pole I_p and the mobile frame $(\mathbf{e}_\varrho, \mathbf{e}_\omega)$. The polar coordinates of P are (ϱ, θ_p) and will be denoted simply by (ϱ, θ) . Let us denote by $y \equiv \varrho \sin \theta$, the distance from the point P to the solid wall. We deduce, $dy = d\varrho \sin \theta + \varrho \cos \theta d\theta$ and due to the differential relation, $dy = dl \sin \theta$, we obtain, $d\varrho/dl = 1 - \varrho \cotg \theta d\theta/dl$. When $\theta \neq 0$ or π , $\lim_{r \rightarrow 0} \varrho \cotg \theta d\theta/dl = 0$ and consequently, when $r \rightarrow 0$, $d\varrho \sim dl$. Let M be another point of C_{t2} ; we denote J_p and J_m the intersections of $C(I_p)$ and $C(I_m)$ with the axis $O\mathbf{n}'_1$; when $M \rightarrow P$, $\|\mathbf{J}_m\mathbf{J}_p\| \sim d\varrho$, $\|\mathbf{I}_m\mathbf{I}_p\| \sim \varrho d\theta/\sin \theta$ and relation (20) implies, $\lim_{r \rightarrow 0} (\|\mathbf{I}_m\mathbf{I}_p\|/\|\mathbf{J}_m\mathbf{J}_p\|) = 0$. Thus, in the immediate vicinity of the point O , $\|\mathbf{I}_m\mathbf{I}_p\| \ll \|\mathbf{J}_m\mathbf{J}_p\|$ and the two arcs of circles $C(I_m)$ and $C(I_p)$ are distinct. In the following, we prove that, *near the point O , a point Q of the fluid domains is represented by the orthogonal coordinate system (ϱ, ω)* . The equation of the curve C_{t2} can be written in the form $\theta = \vartheta(\varrho)$.

As in section 4 for two-dimensional steady flow, the stream function $\Psi(\varrho, \omega)$ verifies $\nabla^4 \Psi = 0$. We look for a stream function in the form

$$\Psi(\varrho, \omega) \equiv \varrho h(\omega, \theta),$$

where $\theta = \vartheta(\varrho)$, and such that the partial derivatives of h with respect to ω and θ are bounded. But,

$$d\mathbf{OQ} = d\mathbf{OI}_p + d\mathbf{I}_p\mathbf{Q} = \left(\frac{\varrho d\theta}{\sin \theta d\varrho} \mathbf{n}'_1 + \mathbf{e}_\varrho \right) d\varrho + \varrho d\omega \mathbf{e}_\omega.$$

Since $\lim_{\varrho \rightarrow 0} \varrho d\theta/d\varrho = 0$ and $\sin \theta \neq 0$, we obtain

$$d\mathbf{OQ} = d\varrho (\mathbf{e}_\varrho + \mathbf{o}_1(\varrho)) + \varrho d\omega \mathbf{e}_\omega, \quad \text{with} \quad \lim_{\varrho \rightarrow 0} \mathbf{o}_1(\varrho) = \mathbf{0},$$

and near the point O

$$d\mathbf{OQ} = d\varrho \mathbf{e}_\varrho + \varrho d\omega \mathbf{e}_\omega.$$

Moreover,

$$\text{grad } \Psi = (h + \varrho \frac{\partial h}{\partial \theta} \frac{d\theta}{d\varrho}) \mathbf{e}_\varrho + \frac{\partial h}{\partial \omega} \mathbf{e}_\omega.$$

and

$$\text{grad } \Psi = (h + o_2(\varrho)) \mathbf{e}_\varrho + \frac{\partial h}{\partial \omega} \mathbf{e}_\omega, \quad \text{with } \lim_{\varrho \rightarrow 0} o_2(\varrho) = 0.$$

The velocity is

$$\mathbf{V} = v_\varrho \mathbf{e}_\varrho + v_\omega \mathbf{e}_\omega + \mathbf{o}_3(\varrho) \quad \text{with, } v_\varrho = -\frac{\partial h}{\partial \omega}, \quad v_\omega = h \quad \text{and, } \lim_{\varrho \rightarrow 0} \mathbf{o}_3(\varrho) = \mathbf{0},$$

and near the contact line

$$\mathbf{V} = v_\varrho \mathbf{e}_\varrho + v_\omega \mathbf{e}_\omega.$$

In the following, $o_n(\varrho)$ with $n \in \mathbb{N}$, denotes a smooth function of the order of ϱ such that $\lim_{\varrho \rightarrow 0} o_n(\varrho) = 0$. Similarly,

$$\nabla^2 \Psi = \text{div grad}(\Psi) = \frac{1}{\varrho} h + \frac{\partial h}{\partial \theta} \frac{d\theta}{d\varrho} + \frac{1}{\varrho} \frac{\partial^2 h}{\partial \omega^2} + \frac{1}{\varrho} o_4(\varrho) = \frac{1}{\varrho} h + \frac{1}{\varrho} \frac{\partial^2 h}{\partial \omega^2} + \frac{1}{\varrho} o_5(\varrho),$$

$$\begin{aligned} \text{grad}(\nabla^2 \Psi) &= \left(-\frac{1}{\varrho^2} \left(h + \frac{\partial^2 h}{\partial \omega^2} \right) + \frac{1}{\varrho} \left(\frac{\partial h}{\partial \theta} + \frac{\partial^3 h}{\partial \omega^2 \partial \theta} \right) \frac{d\theta}{d\varrho} + \frac{1}{\varrho^2} o_6(\varrho) \right) \mathbf{e}_\varrho \\ &+ \frac{1}{\varrho^2} \left(\frac{\partial h}{\partial \omega} + \frac{\partial^3 h}{\partial \omega^3} \right) \mathbf{e}_\omega = \left(-\frac{1}{\varrho^2} \left(h + \frac{\partial^2 h}{\partial \omega^2} \right) + \frac{1}{\varrho^2} o_7(\varrho) \right) \mathbf{e}_\varrho + \frac{1}{\varrho^2} \left(\frac{\partial h}{\partial \omega} + \frac{\partial^3 h}{\partial \omega^3} \right) \mathbf{e}_\omega, \end{aligned}$$

and finally,

$$\begin{aligned} \nabla^4 \Psi &= \frac{1}{\varrho^3} \left(h + \frac{\partial^2 h}{\partial \omega^2} \right) - \frac{1}{\varrho^2} \left(\frac{\partial h}{\partial \theta} + \frac{\partial^3 h}{\partial \omega^2 \partial \theta} \right) \frac{d\theta}{d\varrho} + \frac{1}{\varrho^3} \left(\frac{\partial^2 h}{\partial \omega^2} + \frac{\partial^4 h}{\partial \omega^4} \right) + \frac{1}{\varrho^3} o_8(\varrho) \\ &= \frac{1}{\varrho^3} \left(h + 2 \frac{\partial^2 h}{\partial \omega^2} + \frac{\partial^4 h}{\partial \omega^4} \right) + \frac{1}{\varrho^3} o_9(\varrho), \end{aligned}$$

The principal part of the Laurent expansion in ϱ of $\nabla^4 \Psi$ leads to the partial derivative equation

$$h + 2 \frac{\partial^2 h}{\partial \omega^2} + \frac{\partial^4 h}{\partial \omega^4} = 0,$$

and the general solution for the principal part of Ψ is

$$\Psi(\varrho, \omega) = \varrho (a \sin \omega + b \cos \omega + c \omega \sin \omega + d \omega \cos \omega), \quad (21)$$

where a, b, c, d are functions of θ . When $\mu_A = \mu_B$, the boundary conditions at the solid wall and the conditions (i)-(iv) presented in section 4 yield the

values of coefficients a, b, c, d for the two fluids L_A and L_B . These values are given by relations (13)₂, but here, θ is not constant. The viscous stress components are

$$\tau_{\varrho\omega} = -\frac{\mu}{\varrho}\left(h + \frac{\partial^2 h}{\partial \omega^2}\right) \equiv -2\frac{\mu}{\varrho}(c \cos \omega - d \sin \omega), \quad \tau_{\varrho\varrho} = \tau_{\omega\omega} = 0.$$

As in section 4, the pressure field is given by

$$p = p_0 - 2\frac{\mu}{\varrho}(c \sin \omega + d \cos \omega).$$

In partial wetting, the stream function (21) together with relations (13)₂ show that the partial derivatives of h with respect to ω and θ are bounded along C_{t2} . Along C_{t2} , $p_A - p_B = \sigma_{AB}/R$ and consequently,

$$\frac{\varrho d\theta}{dl} = \frac{\mu u}{\sigma_{AB}} 2\pi \sin \theta D(\theta). \quad (22)$$

Furthermore, $\|\Delta\| = \{1/(2\varrho)\} |h + \partial^2 h / \partial \omega^2|_{\omega=\theta}$. Thus,

$$\|\Delta\| = \frac{|u|}{\varrho} |c_A \cos \theta - d_A \sin \theta| \equiv \frac{|u|}{\varrho} |c_B \cos \theta - d_B \sin \theta| \equiv \frac{|u|}{\varrho} \sin^3 \theta D(\theta).$$

Let us note that, in the frame $(O, \mathbf{n}'_1, \mathbf{n}_1)$, relations $x = \varrho \cos \theta$, $y = \varrho \sin \theta$, $dy = dl \sin \theta$, $\theta_i = \text{Arccos}\{(\sigma_{BS} - \sigma_{AS})/\sigma_{AB}\}$ together with Eq. (22) and relation (15), allow us to obtain the parametric representation of C_{t2} near the solid wall.

Eq. (22) allows us to verify that $\lim_{r \rightarrow 0} r d\theta/dl = 0$ and thus, the choice of the stream function Ψ in the form (21) together with relations (13)₂ is justified in the vicinity of the point O . Let us note that when $u > 0$ (resp. $u < 0$), θ is an increasing (resp. decreasing) function of the distance y of a point of C_{t2} to the solid wall. We do notice also that, whereas the curvature of C_{t2} tends to infinity when the point O is approached, the stream function Ψ has the same form as the stream function ψ proposed in subsection 4.2 for a plane interface (a good example of such a curve is given, near $x = 0$, by $y = |x|^{\frac{3}{2}}$ (Voinov, [35])).

5.2 Apparent dynamic contact angle and line friction

Let A be the point of C_{t2} associated with the cut-off coefficient value γ_0 , defined in subsection 4.2: the point A is at the border between the Newtonian and the non-Newtonian domains of the fluid flows. We call *apparent*

dynamic contact angle θ_a , the value of θ associated with the point A (see fig. 4). Along the fluid-fluid interface, condition $(Q_{Ai}^j - Q_{Bi}^j) n_2^i n_{2j} = 0$, together with relation (12) and $p_B - p_A = (1/\varrho) \mu u 2\pi \sin\theta D(\theta)$, imply

$$\sigma_{AS} - \sigma_{BS} + \sigma_{AB} \cos \theta_a + \nu u = 0, \quad (23)$$

with

$$\nu = \int_0^A \frac{\mu}{\varrho} 2\pi \sin^2\theta D(\theta) dl. \quad (24)$$

Relation (23) is a form of *Young-Dupré dynamic relation for the apparent dynamic contact angle*. We call ν , *the line friction*. It is easy to verify that the scalar ν is positive and of the same physical dimension as a dynamic viscosity. This result corresponds to the assumption in the article of Stokes *et al*, [33], in which they say that *there is an additional viscous force on a moving contact line*. Other expressions for the line friction have also been proposed (an attempt is done by a thermodynamic point of view in Fan, Gao and Huang, [8]).

In the case of equilibrium, relation (23) yields the static Young-Dupré relation (Levitch, [22])

$$\sigma_{AS} - \sigma_{BS} + \sigma_{AB} \cos \theta_e = 0,$$

in which θ_e is the balance Young angle and $\theta_e = \theta_i = \theta_a$. For any value of the contact line celerity, relations (23) and (24) yield, implicitly, the apparent dynamic contact angle θ_a . With the formula (23), a simple explanation of a well-known experimental result (Dussan, [6]), may also be corroborated: with the advance of the contact line, u is positive and the apparent dynamic contact angle θ_a is larger than the equilibrium angle θ_e . This result is reversed when u is negative.

5.3 Numerical investigations of the apparent dynamic contact angle and the line friction

Hoffman, [17], Legait and Sourieau, [21], Ramé and Garoff, [26], and many other authors experimentally observe that, near the contact line, for slow motions, *the apparent dynamic contact angle seems independent of the microscopic distance to the solid surface*. Let us verify numerically this observation.

Using the relations $y = \varrho \sin \theta$ and $dy = dl \sin \theta$, relation (22) implies

$$\frac{dy}{y} = \frac{\sigma_{AB}}{\mu u 2\pi \sin \theta D(\theta)} d\theta.$$

Let us consider a point N of C_{t2} in the Newtonian domain of the fluid flows. Then,

$$\ln\left(\frac{y_n}{y_a}\right) = \int_{\theta_a}^{\theta_n} \frac{\sigma_{AB}}{\mu_0 u 2\pi \sin \theta D(\theta)} d\theta, \quad (25)$$

where y_a and y_n denote the distances of points A and N to the solid wall. In partial wetting, when $\pi/6 < \theta < 5\pi/6$, then $0 < 2\pi \sin \theta D(\theta) < 15$ and if $u > 0$,

$$0 < \theta_n - \theta_a < 15 C_a \ln\left(\frac{y_n}{y_a}\right).$$

If we consider the case when $y_n = 10^4 y_a$, a crude approximation yields $\theta_n - \theta_a < 140 C_a$ and thus $\theta_n - \theta_a$ tends to zero with C_a . For example, when $C_a = 10^{-4}$, we obtain $\theta_n - \theta_a < 0.014$ radian, (i.e. 0.8 degree), and the apparent dynamic contact angle seems independent of the distance of the point N to the solid wall: in the lubrication approximation for two dimensional flows, Eq. (23) expresses the behaviour of the apparent dynamic contact angle independently of any microscopic distance to the contact line. This result is in accordance with Seppecher's calculations [29].

Let us estimate an order of magnitude of the line friction. Along C_{t2} , Eq. (21) implies that, for each fluid, $|h + \partial^2 h / \partial \omega^2|_{\omega=\theta} = |u| 2 \sin^3 \theta D(\theta)$. When $\xi = 0.1$, a numerical computation yields

$$\frac{\pi}{6} < \theta < \frac{5\pi}{6} \Rightarrow 1.015 |u|^\xi < |h + \frac{\partial^2 h}{\partial \omega^2}|_{\omega=\theta}^\xi < 1.032 |u|^\xi.$$

Taking into account the norm $\|\mathbf{\Delta}\|$ of the strain rate tensor along C_{t2} , relation (15) yields a value of γ such that

$$\gamma \simeq \frac{1}{1.02} \left(\frac{2 \varrho}{\tau_0 u} \right)^\xi,$$

and $d\gamma/\gamma = \xi d\varrho/\varrho$. Then, relation (24) allows us to obtain the value of the line friction

$$\nu = \frac{2\pi\mu_0}{\xi} \int_0^{\gamma_0} \sin^2 \theta D(\theta) \frac{1 - e^{-\gamma}}{\gamma} d\gamma.$$

Since $\sin^2 \theta D(\theta) > 0$, we obtain

$$\nu = \frac{2\pi\mu_0}{\xi} \sin^2 \theta_r D(\theta_r) \int_0^{\gamma_0} \frac{1 - e^{-\gamma}}{\gamma} d\gamma, \quad \text{with } \theta_r \in [\theta_i, \theta_a]$$

in which θ_r is a convenient angle. Due to $\int_0^{\gamma_0} (1/\gamma)(1 - e^{-\gamma}) d\gamma \simeq 1$, we obtain

$$\nu = \frac{2\pi\mu_0}{\xi} \sin^2 \theta_r D(\theta_r).$$

In partial wetting, a numerical computation implies

$$\frac{\pi}{6} < \theta_r < \frac{5\pi}{6} \Rightarrow 0.68 < \sin^2 \theta_r D(\theta_r) < 1.17,$$

and consequently

$$42 \mu_0 < \nu < 73 \mu_0. \quad (26)$$

Eq. (10) and Eq. (23) imply $|\cos \theta_a - \cos \theta_i| < \nu |u|/\sigma_{AB}$. Taking into account inequalities (26), we obtain $|\cos \theta_a - \cos \theta_i| < 73 C_a$. In the partial wetting case, for $\theta \in (\pi/6, 5\pi/6)$, then $|\sin((\theta_a - \theta_i)/2)| < 73 C_a$ and the derivative of $\sin^2 \theta D(\theta)$ belongs to $(-1, 1)$; we can deduce $|\sin^2 \theta_r D(\theta_r) - \sin^2 \theta_a D(\theta_a)| < 2 \text{Arcsin}(73 C_a)$. This crude approximation proves that for C_a sufficiently small, $\sin^2 \theta_r D(\theta_r)$ is close to $\sin^2 \theta_a D(\theta_a)$ (for example, when $C_a = 10^{-4}$, we obtain $|\sin^2 \theta_r D(\theta_r) - \sin^2 \theta_a D(\theta_a)| < 0.015$). Replacing $D(\theta_a)$ by its explicit expression sets the approximative relation of the line friction :

$$\nu = \frac{2\pi\mu_0}{\xi} \left(\frac{\sin^2 \theta_a}{\theta_a (\pi - \theta_a) - (\pi - 2\theta_a) \sin \theta_a \cos \theta_a - \sin^2 \theta_a} \right). \quad (27)$$

6 Concluding remarks

In this paper, the dynamical problem of the contact of two non-Newtonian viscous fluids L_A and L_B with a solid was analyzed. Except at the contact line, these fluids were assumed to adhere to the solid and to each other. Then, the principle of virtual work allows us to obtain the governing equations and boundary conditions. It was shown that the equations of motions and boundary conditions lead to streamlines near the contact line similar to those of a Newtonian fluid endowed with a dynamic viscosity which is, when the strain rate tensor tends to zero, the limit of the dynamic viscosity of the non-Newtonian fluid. The analyze of the stress tensor and the dissipative function near the contact line leads to several remarks and conclusions:

For dissipative movements, a viscous stress tensor Q_i^j was added to the pressure term and in the expression of virtual work, the dissipative terms were distributed within the volume as $Q_{i,j}^j$ and on the surfaces as $-Q_i^j n_{\alpha j}$. In magnitude, the surface tension is comparable with the bulk stress despite the fact that the thickness of the interfacial layer, where the surface tension acts, is negligible compared to the characteristic length scale in the bulk: although the interfacial layer is very thin, the intermolecular forces which act on it and give rise to the surface tension are very strong so that the

result is finite. Huge variations of the fluid velocity appear at the three-phase contact line. The only physical factor, which achieves to *magnify* its role, does not come from intermolecular forces but from the *discontinuity* of the velocity at the contact line and consequently from the viscosity along the contact line when the thickness of the contact line region tends to zero. In the immediate vicinity of the contact line, the viscous stresses yield a friction force which acts on the fluid-fluid interface and is balanced by strong capillary tensions associated with the curvature of the fluid-fluid interface. Consequently, expression (23) introduces a new term associated with the contact line Γ_t .

Creeping flow of a Newtonian fluid is unrealistic at the corner of a moving contact line. Nevertheless, the system that is based on Eq. (4), boundary conditions (5), (6), adherence assumption on solid surfaces together with the dynamic Young-Dupré relation (23) for the apparent contact angle which *accommodates the behaviour of the non-Newtonian fluid domain* in the immediate vicinity of the contact line poses a problem of slow fluid motion. This result, in agreement with experiments and molecular investigations, is brought out by means of the analytic representation of the streamlines on Newtonian behaviour; *however, other non-Newtonian fluid behaviour is used to arrive at bounded dissipative functions near the contact line.*

For slow movements we are able to give a model which provides answers to the previous questions:

- The contact line is a non material line and acts in a similar way as a *shock line*.
- The velocity fields are multivalued on the line.
- The paradox of infinite viscous dissipation is removed.
- Adherence and boundary conditions on surfaces and interfaces are preserved, but a dynamic Young-Dupré relation derived by the virtual work principle yields the apparent dynamic contact angle as an implicit function of the contact line celerity. The apparent dynamic contact angle is the only pertinent Young angle from a continuum mechanics point of view.
- For partial wetting, and for a sufficiently small capillary number, the concept of line friction is associated with the apparent contact angle.

The contact angle hysteresis phenomenon and the modelling of experimentally well-known results that express the dependence of the dynamic contact angle on the celerity of the line are important phenomena. In part 2, Eq. (23) allows us to obtain an explanation of the contact-angle hysteresis in the advance and retreat of slowly moving fluids on a solid surface.

Acknowledgments

I am grateful to Professor Seppecher and Professor Teshukov for their helpful discussions about theoretical developments. I am indebted to Professor Hutter and the anonymous referees for much valuable criticism during the review process.
